Abstract

In this paper, we present an approach to model focus of attention of participants in a meeting via hidden Markov models (HMM). We employ HMM to encode and track focus of attention, based on the participants' gaze information and knowledge of their positions. The positions of the participants are detected by face tracking in the view of a panoramic camera mounted on the meeting table. We use neural networks to estimate the participants' gaze from camera images. We discuss the implementation of the approach in detail, including system architecture, data collection, and evaluation. The system has achieved an accuracy rate of up to 93 % in detecting focus of attention on test sequences taken from meetings. We have used focus of attention as an index in a multimedia meeting browser.

1 Introduction

It is well known that non-verbal communication cues play an important role during social interaction [14, 1]. Such non-verbal cues include body posture, facial expressions, gestures and gaze. In this research we are interested in tracking at whom or what a person is looking during a meeting. This information can be used to determine message target(s) during the meeting and index recorded meetings.

We propose to employ Hidden Markov Models (HMM) to characterize the participants' focus of attention based on their gaze information and the knowledge of their positions in the meeting room. The positions of participants are detected by tracking their faces from a panoramic camera mounted on the meeting table. The faces that appear in the view of the camera are located and transformed into perspective view images. We use neural networks to estimate the participants' gaze. The HMMs determine focus of attention and filter out random noise. We discuss the implementation of the approach in detail including system architecture, data collection, and evaluation.

Tracking a person's focus of attention is useful in several application areas: Intelligent supportive computer applications could use information about a user's focus of attention to get an understanding of the user's internal state, his goals and cognitive load and adjust their own responses to the user accordingly. For multimodal human computer interaction, the user's focus of attention can be used to determine his/her message target. For example in interactive intelligent rooms or houses [6, 2], focus of attention could be used to determine whether the user is speaking a command to the refrigerator, his TV set, or whether he is talking to another person in the room. In computer mediated communication systems, such as virtual collaborative workspaces, detecting and conveying participants' gazes have several advantages: it can help the participants to determine who is talking or listening to whom, it can serve to establish joint attention during cooperative work and it can facilitate turn taking among participants [12, 4].

The remainder of the paper is organized as follows: In section 2 we introduce our approach to model a person's focus of attention in a meeting. In section 3 we discuss how we use neural networks to estimate people's gaze. Section 4 describes the use of a panoramic camera to locate and track the participants around a meeting table. In section 5 we evaluate the proposed focus of attention model on test sequences and discuss details of the model. In section 6 we present an application of the proposed model to a multimedia meeting browser. We summarize the paper in section 7.

2 Modeling Focus of Attention

The objective of this research is to track the focus of attention of participants in a meeting. Since a person's gaze direction is closely related to the person's attention, a first step is to track the person's gaze. However, attention does not necessarily coincide with gaze, since it is a perceptual variable, as opposed to a physical one (head or eye positioning). Our approach to modeling focus of attention attempts to model both, a person's head movements as well as

the relative positions of probable targets of interest in a room. In a meeting, as depicted in Figure 1, clearly the participants around the table are such likely targets. Other likely targets can be: documents on the table, a whiteboard or slide projections on a wall, or people entering the room. Therefore, our approach

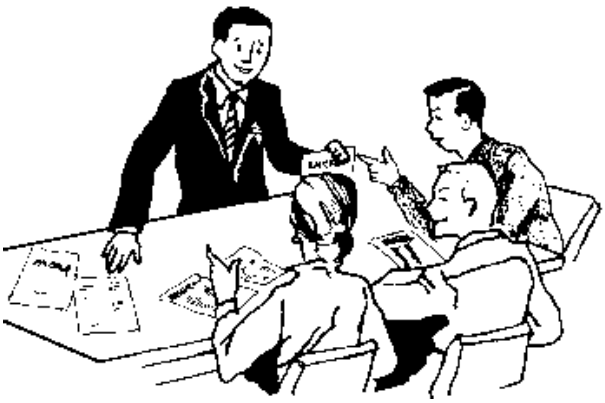

Figure 1: An example of interaction between people in a meeting

to determine all participants' focus of attention is the following:

1. Detect and track all participants around the table
2. Estimate each participants' gaze direction
3. Map the participants' observed gaze to the likely target (the other participants) using a probablistic framework

HMMs can provide such an integrated framework for probabilistically interpreting observed signals over time. In our model, looking at a certain target is modeled as being in a certain state of the HMM and the observed gaze estimates are considered as being probabilistic functions of the different states. Given this model and an observation sequence of gaze directions, it is then possible to find the most likely sequence of HMM states that produced the observations. By interpreting being in a certain state as looking at a certain target, it is now possible to estimate a person's focus of attention in each frame.

While a person's gaze is determined by the person's head orientation as well as his/her eye-gaze, we only consider head gaze as the main indicator of a person's gaze. The reason for doing this, is that we want to build a system with minimum intrusion. Without the use of head mounted cameras, infrared eye-trackers or other expensive equipment for each participant and with users that are allowed to move freely, it would be very difficult to track eye-gaze of all users. To obtain the gaze observations needed for our model, we have trained neural networks to estimate a person's head pose from facial images, which are automatically extracted from camera images using a color- and motion-based face tracker.

To determine the number of HMM states necessary for each person's attention model, i.e. the number of other participants at the table, we use a face tracker to locate all faces in the view of a panoramic camera that is put on top of the conference table. The relative position of the found faces is later used to map each of the HMM states to a specific participant of the meeting.

3 Estimating Head Pose Using Neural Nets

In this section we describe our procedures of using neural networks to estimate a person's gaze from facial images.

A major advantage of using neural networks to estimate head pose as compared to using a model based approach is its robustness: With model based approaches to head pose estimation [3, 11, 5], head pose is computed by finding correspondences between facial landmarks points (such as eyes, nostrils, lip corners) in the image and their respective locations in a head model. Therefore these approaches rely on tracking a minimum number of facial landmark points in the image correctly, which is a difficult task and likely to fail. On the other hand, the neural network-based approach doesn't require tracking detailed facial features because the whole facial region is used for estimating the user's head pose.

In our approach we are using neural networks to estimate pan and tilt of a person's head, given automatically extracted and preprocessed facial images as input to the neural net. Our approach is similar to the approach as described by Schiele and Waibel [9]. However, the system described in [9] estimated only head rotation in pan direction. In this research we use neural network to estimate head rotation in both pan and tilt directions. In addition, we have studied two different image preprocessing approaches. Rae and Ritter [8] describe a user dependent neural network based system to estimate pan and tilt of a person. In their approach, color segmentation, ellipse fitting and Gabor-filtering on a segmented face are used for preprocessing. They report an average accuracy of 9 degrees for pan and 7 degrees for tilt for one user with

a user dependent system.

The work presented in this section extends our previously published work on neural net based head pose estimation [10] in the following ways: whereas we have only used training data that was collected in one room for our previous system, we have used data that was collected in two rooms and under significantly different lighting conditions here. Also we have changed the network architecture here. Whereas we have used separate nets with gaussian output representation to estimate pan and tilt previously, we have now used one net to estimate both, pan and tilt. Only two output units, for pan and tilt respectively are used.

3.1 Data Collection

We collected training data from nineteen persons in two different rooms with different lighting conditions. During data collection, users had to wear a head band with a sensor of a Polhemus pose tracker attached to it. Using the pose tracker, the head pose with respect to a magnetic transmitter could be collected in real-time. A camera was positioned approximately 1.5 meters in front of the users head. The user was asked to randomly look around in the room and the images together with the pose sensor readings were recorded. Figure 2 shows two sample images of the same user taken under different lighting conditions during data collection.

Figure 2: Two images of the same person taken in two rooms during data collection

3.2 Preprocessing of Images

To locate and extract the faces from the collected images, we use a statistical skin color model [15]. The largest skin colored region in the input image is selected as the face.

We have investigated two different image preprocessing methods as input to the neural nets for pose estimation [10]: 1) Using normalized grayscale images of the user's face as input and 2) applying edge detection to the images before feeding them into the nets.

In the first preprocessing approach, histogram normalization is applied to the grayscale face images as a means towards normalizing against different lighting conditions. No additional feature extraction is performed. The normalized grayscale images are downsampled to a fixed size of 20x30 pixels and then are used as input to the nets.

In the second approach, a horizontal and a vertical edge operator plus thresholding is applied to the facial grayscale images. The resulting edge images are downsampled to 20x30 pixels and are both used as input to the neural nets.

Since we obtained the best results when combining the histogram normalized and the edge images as input to the neural nets [10], we are only presenting results using this combination of differently preprocessed images as input to the neural net here.

Figure 3 shows the corresponding preprocessed facial images of a user. From left to right, the normalized grayscale image, the horizontal and vertical edge images of a user's face are depicted.

Figure 3: Preprocessed images: normalized grayscale, horizontal edge and vertical edge image (from left to right)

3.3 Neural Net Architecture, Training and Results

We have trained one net to estimate both, pan and tilt of the head. We have used a multilayer perceptron architecture with two output units (for pan and tilt), one hidden layer with thirty units and an input retina of 20x90 units for the three input images of size 20x30 pixels. Output activations for pan and tilt were normalized to vary between zero and one. Training of the neural net was done using standard backpropagation.

3.3.1 Results with Multi-User System

To train a multi-user neural network, we divided the data set of the nineteen users into a training set consisting of 11.500 images, a cross-evaluation set of size 1.500 images and a test set with a size of 1.500 images. After training, we achieved a mean error of 8.8 degrees for pan and 5.7 degrees for tilt on the test set.

3.3.2 User Independent Results

To determine how well the neural net based system can generalize to new users, we have also trained one net on seventeen users and evaluated it on the remaining two users, that have not been in the training set. Table 1 shows the results that we obtained for the two new users. On average we received an error of 11 degrees for pan and 10 degrees for tilt on the new users.

	E_{pan}	E_{tilt}
subject A	11.5	11.3
subject B	9.6	8.5
Average	10.6	9.9

Table 1: Person independent results (mean error in degrees) for two new users

3.3.3 Evaluating the Effect of Different Lighting Conditions

To evaluate the effect of images taken under different lighting conditions, we also trained and evaluated neural nets that were only trained with images from one room. Table 2 shows the results that we obtained using these "room-dependent" nets when testing on images from the same room versus testing with images from the other room.

Training Data	Test Data	E_{pan}	E_{tilt}
Room 1	Room 1	8.0	5.1
Room 2	Room 2	9.2	5.3
Room 1	Room 2	21.4	18.2
Room 2	Room 1	20.1	18.7
Room 1,2	Room 1,2	8.8	5.7

Table 2: Results obtained when training and testing on images taken under different lighting conditions

It can be seen, that the accuracy of the pose estimation dramatically decreases when testing the nets on images that were taken under different lighting conditions than during training. However, when using images from both rooms during training, the pose estimation results remain stable.

4 Detecting and Tracking All Participants Using a Panoramic Camera

In order to assign one HMM state to each of the other participant at the table in our focus of attention model as described in section 2, it is necessary to determine the number and relative locations of participants that are apparent around the conference table.

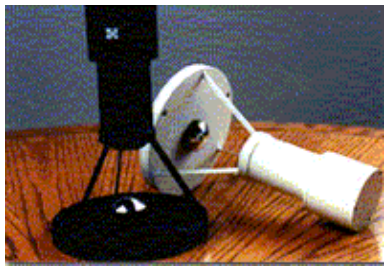

Figure 5: The panoramic camera used to capture the scene[1]

We are using a panoramic camera with a 360 degree field of view that we put on top of the conference table to capture the whole scene around the table. Figure 5 shows a picture of the panoramic camera system that we are using. The camera is located in the top cylinder and is focusing on a parabolic mirror on the bottom plate. Through this mirror almost a whole hemisphere of the surrounding scene is visible. Figure 6 shows the view of a meeting scene as it is seen in the parabolic mirror and as it is captured with this camera. As the topology of the mirror and the optical system are known, it is possible to compute rectified panoramic views of the scene as well as perspective views in different viewing directions. This can easily be done in real time. Figure 4 shows the rectified panoramic image (with faces marked) of the camera view depicted in Figure 6.

4.1 Using Color and Motion for Face Detection

To detect and track faces in the panoramic camera view, a statistical skin color model consisting of a two-dimensional Gaussian distribution of normalized skin colors is used. The color distribution is initialized so as to find a variety of face colors and is gradually adapted to the faces actually found. The interested reader is referred to [15]. To detect faces, the input image is searched for pixels with skin colors. Connected regions of skin-colored pixels in the camera image are considered as possible faces.

Since humans rarely sit perfectly still for a long time, motion detection is used to reject outliers that might be caused due to noise in the image or skin-like

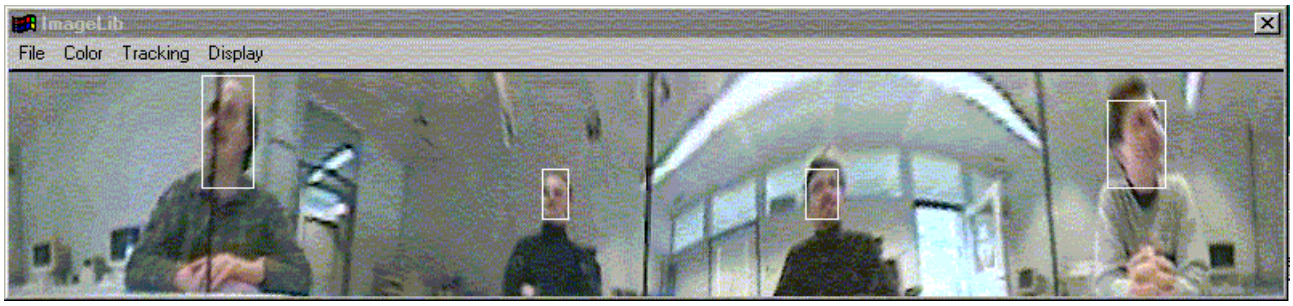

Figure 4: Panoramic view of the scene around the conference table. Faces are automatically detected and tracked (marked with boxes).

Figure 6: Meeting scene as captured with the panoramic camera

objects in the background of the scene that are not faces or hands. Only regions with a response from the color-classifier and some motion during a period of time are considered as faces.

Using only this approach however, faces and hands are not yet distinguished sufficiently. We are therefore considering skin-colored regions as belonging to the same person if the projection of their centers onto the x-axis are close enough together. Among the candidate regions belonging to one person, we consider the uppermost skin-like region to be the face and consider the lower skin-like region to be hands. Figure 4 shows a sample panoramic image with the four found faces marked with white boxes. Note the hands apparent in the panoramic view, which are not considered to be faces (and therefore not marked here).

5 Experimental Evaluation of the Model

To evaluate our focus of attention model, we have recorded videos during several meetings. During these meetings we have captured all participants with a panoramic camera as described in section 4. In addition, two cameras were used to capture images from two of the meeting participants. Since we have not (yet) trained neural nets to estimate head pose from perspective images that can be generated from the panoramic view, the additional cameras are needed to obtain the facial images as input to our neural net based head pose estimation. Figure 7 shows some example images taken with the additional cameras during one of the meetings.

5.1 Initialization of the HMMs

To determine the number of states of each HMM, the number of participants of the meeting is automatically detected in the panoramic image as described in section 4. Since for each person we are are considering the other participants as likely focus of attention targets, we are assigning each of the other participants to one state of the Hidden Markov Model.

We have parameterized the state dependent observation probabilities $B = b_i(\omega)$ for each state i, where $i \in \{Person_1, Person_2, \ldots, Person_n\}$, as two-dimensional gaussian distributions with diagonal covariance matrices:

$$b_i(\omega) = \frac{1}{2\,\pi\,\sqrt{\sigma_{pan}\,\sigma_{tilt}}} e^{-\frac{1}{2}\left[\frac{(\omega_{pan}-\mu_{pan})^2}{\sigma_{pan}^2}+\frac{(\omega_{tilt}-\mu_{tilt})^2}{\sigma_{tilt}^2}\right]}$$

The observable symbols ω are the pose estimation results that we obtain using the neural net based head pose estimation as described in section 3, that is the angles for pan and tilt ω_{pan} and ω_{tilt}.

Using the relative locations of participants that we have found in the panoramic view, we could initial-

Figure 7: Sample sequence taken during a meeting

ized the observation probability distributions of the different states with the means of the gaussians set to the expected viewing angle, when looking at the corresponding target.

However, gaze is not only determined by head pose but also by the direction of eye gaze. People not always completely turn their head towards the person that they are looking at, instead they are also using their eye gaze direction. On our meeting recordings we observed that some people are using their head quiet strongly, others are stronger relying on eye gaze and only are turning their heads slightly when looking at others. We are therefore using an unsupervised learning approach to find the head pan of a user when he is looking at the other participants. Knowing that the user is likely to look at his participants during the meeting, we can find clusters in the gaze observations of this user. These gaze observations can be clustered to the number of classes corresponding to the known number of other participants. The found means of these classes can then be assigned to each participant based on his relative location at the table. Table 3 shows the mean pan-observations for four participants in a meeting, that we found using hierarchical clustering on the gaze observations of the participants and that we used to initialize the HMM for the respective person. The transition matrix $\mathbf{A} = (a_{ij})$ was

	μ_1	μ_2	μ_3
Person A	-35.1	-7.1	20.9
Person B	-26.3	16.3	36.8
Person C	-26.4	-5.6	13.2
Person D	-19.9	-5.2	12.4

Table 3: Means of clusters found in head pan observations for four different users (in degrees)

initialized to have higher transition probabilities for remaining in the same state ($a_{ii} = 0.5$) and uniformly distributed state transition probabilities for all other transitions. The initial state distribution was chosen to be uniform.

5.2 Finding the Best Sequence

Let $O = \omega_1\omega_2\cdots\omega_T$ be the sequence of gaze direction observations $\omega_t = (\omega_{pan,t}, \omega_{tilt,t})$ as predicted by the neural nets. The probability of the observation sequence given the HMM is given by the sum over all possible state sequences q:

$$\begin{aligned} p(\mathbf{O}) &= \sum_q p(O,q) \\ &= \sum_q p(O|q)\ p(q) \\ &\approx \sum_q \prod_t p(\omega_t|q_t)\ p(q_t|q_{t-1}) \\ &= \sum_q \prod_t b_{q_t}(\omega)\ a_{q_t,q_{t-1}}. \end{aligned}$$

To find the single best state sequence of foci of attention, $q = q_1 \ldots q_n$ for a given observation sequence, we need to find

$$max_q(p(O,q)).$$

This can be efficiently computed by the Viterbi algorithm [7]. Thus, given the HMM and the observation sequence of gaze directions, we can efficiently find the sequence of foci of attention using the Viterbi algorithm.

To evaluate the performance of the proposed model, we compared the state-sequence given by the Viterbi-decoding to hand-made labels of where the person was looking to. The evaluated sequences contained 240 frames and lasted for two minutes each. Table 4 shows the results that we obtained on videos from six users. As compared to the hand-labels we obtained an average error of 24 % frames on the six test sequences.

5.3 Unsupervised Adaptation of Model Parameters

It is furthermore possible to adapt the model parameters $\lambda = (\mathbf{A}, \mathbf{B})$ of the HMM so as to maximize $p(O|\lambda)$. This can be done in the EM (Expectation-Maximization) framework by iteratively computing

Sequence	Error
A	26 %
B	21 %
C	30 %
D	11 %
E	22 %
F	32 %
Average	24 %

Table 4: Results of focus of attention labeling after Viterbi-decoding on six test sequences

Seq.	λ fixed	λ adapted	error reduct.
A	26 %	16 %	31 %
B	21 %	15 %	29 %
C	30 %	30 %	-
D	11 %	7 %	36 %
E	22 %	19 %	14 %
F	32 %	32 %	-
Avg.	24 %	20 %	17 %

Table 5: Percentage of falsely labeled frames for six users without and with reestimation of means and variances

the most likely state sequence and adapting the model parameters as follows:

- means:

$$\hat{\mu}_{pan}(i) = E_i(\omega_{pan}) = \frac{\sum \phi_{i,t}\,\omega_{pan,t}}{\sum \phi_{i,t}}$$

$$\hat{\mu}_{tilt}(i) = E_i(\omega_{tilt}) = \frac{\sum \phi_{i,t}\,\omega_{tilt,t}}{\sum \phi_{i,t}}$$

, where $\phi_{i,t} = \begin{cases} 1 & : \quad q_t = i \\ 0 & : \quad otherwise \end{cases}$

- variances:

$$\sigma^2_{pan}(i) = E_i(\omega^2_{pan}) - (E_i(\omega_{pan}))^2$$
$$\sigma^2_{tilt}(i) = E_i(\omega^2_{tilt}) - (E_i(\omega_{tilt}))^2$$

- transition probabilities:

$$a_{i,j} = \frac{\text{number of transition from state } i \text{ to } j}{\sum_t \phi_{i,t}}$$

Using these formulas, we have automatically adapted the means and variances of the HMM states to the six test sequences. Table 5 shows the results that we obtained after adapting the parameters. The results indicate that the average error obtained after parameter adaptation is 20 % as compared to 24 % error without parameter adaptation. This corresponds to an error reduction of 17 %.

6 Integrating Focus of Attention Modeling into a Meeting Browser

We have integrated the focus of attention model into the "Meeting Browser" - a system to track and summarize meetings [13]. The Meeting Browser is a system designed to automatically review and search recordings of meetings. The browser is implemented in Java and includes video capture of the individuals in the meeting, as pictured in Figure 8. It consists of four major components: 1) a speech recognition component, 2) the summarizer, 3) a discourse component that attempts to identify the speech acts and 4) the component to track the participants' focus of attention. The Meeting Browser is part of a multimodal meeting room. The goal of this project is not only to provide a tool to record and transcribe spoken content of the meetings, but to also detect who participated in the meeting and who was talking when and to whom. The system can automatically produce transcriptions and summaries from meetings.

With the components described in this paper, it is possible to detect the number and positions of participants in a meeting as well as to track which person at the table each of the participants look at. These visual cues can be used for searching in the transcriptions and summaries of meetings and can be useful to determine who a speaker was addressing or focusing on.

7 Conclusion

In this paper we have addressed the problem of tracking focus of attention of the participants in a meeting. We have described how our system automatically locates and tracks the participants in the field of view of a panoramic camera. We have proposed the use of a HMM framework to detect focus of attention from a trajectory of gaze observations and have evaluated the proposed approach on several video sequences recorded during meetings.

For gaze tracking, we have employed neural networks to estimate head pose from facial images. We have obtained mean error as small as 9 degrees for pan

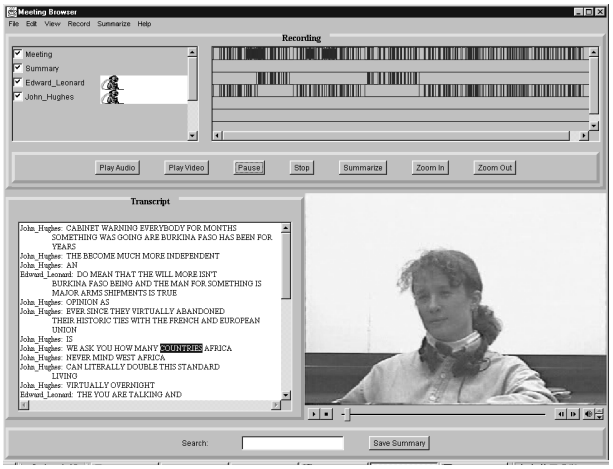

Figure 8: Meeting Browser with video capture

and 6 degrees for tilt with a multi-user neural network that was tested on nineteen users.

We have integrated a module to track focus of attention into a meeting browser - a system which can automatically produce transcriptions and summaries of meetings. The visual cues given by the attention model can be used for indexing the transcriptions and summaries.

Other application areas of tracking focus of attention include: multimodal human computer interfaces, computer supported collaborative work, and interactive intelligent environments.
